The Mismeasure of Man: Why Intergenerational Occupational Mobility is Much Lower than Conventionally Measured, England, 1800-2021

Gregory Clark, Neil Cummins and Matthew Curtis^{*}

May 28, 2022

Abstract

Using a new database of 1.7 m marriages in England 1837-1939, and a genealogy of 414,000 people in England 1700-2021, we estimate two independent new occupational status indices for England 1800-1939. These new indices show that there was much less social mobility 1800-1939 than previous indices, such as HISCAM, imply. The performance of these two new indices, however, illustrates a general problem with comparing social mobility across time and place using status indices. All such indices embody unknown and varying degrees of error. The more error, the more apparent mobility. So in the paper we develop a way of measuring intergenerational occupational status mobility which eliminates all measurement error. This suggests that occupational status persistence in England 1800-2021 was always much greater than conventionally measured, and was largely unchanged over time.

1 Introduction

There has long been interest in sociology and economics in measuring intergenerational social mobility rates, and in comparing these rates across time, and across societies. This has led to the construction of such social status indices as CAMSIS and HISCAM.¹ Using such indices, researchers have compared social mobility rates across countries (Lambert et al. (2013); Long and Ferrie (2018)), and across time within a country (Prandy and Bottero (2000); Song et al. (2020)). These studies suggest two things. The first is that there is typically substantial intergenerational occupational status mobility. The typical correlation of occupational status between father and son is less than 0.5. The second is that there are significant variations in occupational status mobility across time and place.

A recent study, for example, of intergenerational occupational status correlations for the USA for men born 1830-1980 found the results shown in figure 1.1 (Song et al. (2020)). This suggests rapid social mobility all the way from those born 1830 to 1980, with intergenerational correlations almost always less than 0.35. But also we see a clear decline in social mobility between the nineteenth century and the modern period. Similarly Ferrie and Long directly estimate occupational mobility for England 1851-1911, using census data, and imputing average earnings for each occupation as a measure of status. They find for 1851-1911 that the intergenerational correlation of status in England was then 0.27, compared to 0.23 in the USA (Long and Ferrie (2018), table 5).

Lambert et al. (2013) give measures of the father-son correlation using the HISCAM-U2 index for all 8 countries that the U2 index is estimated from, for marriages 1800-1938. This is shown in table 1.1. These correlations, which are typical of the social mobility literature, are in the range of 0.4-0.5 for the whole population, though higher if we restrict to non-farm occupations. But here we see substantial variations in social mobility rates across countries, with Sweden, for example, showing much more mobility than Germany.

Countries	All Men	Non-farm
All	.43	.55
Netherlands	45	56
Germany	.54	.63
France	.44	.54
Sweden	.30	.43
Britain	.46	.50
Canada	.41	.53
Belgium	.43	.48

Table 1.1: Intergenerational Correlations with HISCAM-U2, 1800-1938 *Source*: Lambert et al. (2013), table 2.

However, a problem with all these measures is that the occupational status indices used embody substantial errors. As occupations change over time, the importance of these errors can also change, giving spurious impressions of changes in social mobility rates. Similarly countries that at the same time show large differences in occupational structure can record different degrees of social mobility. In this paper we show that if social status indices are constructed using much larger amounts of data they will indeed show much less social mobility. Also just changing the list of occupation categories used will also change the measured rates of social mobility. All comparisons of social mobility rates across time and place using such indices are thus suspect.

Recognizing these measurement issues, some researchers on social mobility have favored more abstract measures of movement between social status categories, where social status by category is not parameterized, such as the Altham Index (Altham (1970); Altham and Ferrie (2007); Long and Ferrie (2013); Perez (2019)). But, as has been noted, "one possible reason for the lack of success of the Altham index may be difficulty in interpreting it" (Bouchet-Valat (2022, p.205)). Further, any exercise in measuring social mobility that has to assign different occupations or educations to a limited set of social categories, as with the Altham Index, still faces exactly the same problem of different measurement errors across time and space.

In the final section of the paper we suggest a way of measuring intergenerational occupational status mobility rates which is independent of measurement errors. This measure looks at the ratio of the correlation of status between fathers and fathers-in-law relative to that between son and father-in-law. Whatever the errors in status attribution to occupations, this ratio should measure the underlying intergenerational correlation in occupational status. This new measure suggests occupational status mobility rates are substantially lower than conventionally measured. These measurees suggest also that intergenerational occupational status correlations were constant across the interval 1837-2021.

We do however validate in the paper that the HISCAM association methodology does successfully capture the socio-economic status of occupations. These indices do a good job in measuring social status, we shall see, in part because assortment in marriage by occupational status is so strong, so that status can be well captured by such relationship pairs as husband-wife, son-father, and son father-in-law.

2 CAMSIS and HISCAM

The CAMSIS occupational scales for men and women in Britain 1971, 1991, and 2010-12 were derived using data on pairs of occupations for husbands and wives, where both had an occupation. An algorithm was employed to give status scores to each occupation in a way that maximized the resultant marital correlation of occupational status.

HISCAM measures for Britain 1800-1938 were derived in a similar way, but using mainly father-son occupational pairings as the basic data.² Again the algorithm assigns status scores in such a way as to maximize father-son correlations. The number of occupational pairs that each index was based on is given in Table 2.1. As can be seen, for Britain, relative to the number of occupational categories used, the data is modest, so that for many of the less frequent occupational categories the assigned status will be measured with significant error.

Occupations for the HISCAM status scores were coded to a standard set using an international

²http://www.camsis.stir.ac.uk/hiscam/. HISCAM is "an empirical estimate of the average relative position within the structure of social stratification occupied by the incumbents of occupational unit groups" based on "patterns of intergenerational occupational connections."

Index	Occupational Coding	Years	Occupational Categories	Occupational Pairings
HISCAM-GB CAMSIS	HISCO SOC70	1800-1938 1971	1,300	51,419 94.615
CAMSIS	SOC90	1991	371	92,021
CAMSIS	SOC2010	2010-12	371	67,315

Table 2.1: Existing Occupational Indices, Britain

occupation classification system HISCO, which set out to have an internationally comparable set of occupation codes based on the 1,300 most common male and female occupations 1800-1938 in Belgium, England, France, Germany, Netherlands, Norway, Quebec, and Sweden.³ The USA is not included among the HISCAM indices because the creators "have not yet been able to achieve satisfactory results" using US data.⁴ Because of the desire for a comparable international coding of occupations the occupational classifications are detailed. A weaver, for example, can be coded as Cloth Weaver (hand), Cloth Weaver (Machine, except Jacquard Loom), Cloth Weaver (Hand or Machine), Weaver, Specialisation Unknown or Other Weavers and Related Workers.

To rank occupations on a single status scale CAMSIS and HISCAM use Goodman's RCII association model (Goodman (1979)).⁵ As noted above, this is fitted by iterating to a set of occupational rankings that maximize either the correlation of occupational status in marriage, or in father-son pairings. HISCAM-GB is estimated using this RCII model (Lambert et al. (2013)). The resulting estimates are normalized to have mean 50 and standard deviation 15, then truncated to have a minimum value of 1 and a maximum of 99.

However, the HISCAM and CAMSIS indices have two modifications to address several common practical problems in estimating association models. The first is that of sparse categories. The fine grid of occupations, together with the modest numbers of occupational pairings, shown in table 2, means that many occupations appear infrequently. Where an occupational category has few individuals, the RCII estimator often will not converge to a stable set of occupational status rankings. HISCAM and CAMSIS address this by combining any occupation with fewer than 30 observations with other "similar" occupations.⁶ But this, of course, necessitates some a priori judgement of what occupational statuses are, and introduces further error into the indices.

The second problem are so-called "diagonals" and "pseudo-diagonals". Diagonals are cases where each person in the pair has the same occupation. Pseudo-diagonals are cases where even though the occupation have different statuses, they are frequently found together in pairings. These would include particularly "farmer" and "farm-worker" which are found commonly both in husband-wife pairings, and also father-son pairings. To avoid the distortions in status rankings CAMSIS and HISCAM typically drop pairs of diagonals and pseudo-diagonals. The HISCAM project, however, concluded that dropping diagonals was insufficient, and dropped the agricultural sector from their analysis entirely. Farm jobs were assigned scores equal to the average of all occupations paired with farming occupations. With the huge amount of new data assembled below we find that these two problems do not arise, and we can estimate RCII models without any restrictions or ad hoc adjustments.

3 New Occupational Status Indices, England, 1800-1939

Using two large new databases, in this paper we construct two new occupational status indices for men in England 1800-1939. The first of these new indices, FOE-RCII, is an association index, as with CAMSIS and HISCAM. However, in this case it is based on occupational data for 2.36m. father-son and father-son in law pairs, from 1.6 million marriages 1837-1939. We also employ a simplified occupational scheme with 442 occupational categories (as opposed to the 1,300 in HISCAM).

This new index is thus based on nearly 50 times as much data as the HISCAM-GB index. This also uses more father-son pairs than in the entire eight country HISCAM occupational database.⁷ Because of this much greater set of data we are able to avoid most of the ad hoc procedures forced on the HISCAM creators by data limitations, such as amalgamating occupations in the estimation. Because of the much greater occupational status information in occupational titles within English agriculture, we can also estimate the model without having to drop occupations in the agricultural sector. Lastly we are able to implement the RCII model without dropping diagonal, or quasi-diagonal, observations.

³HISCO, or Historical ISCO, is a modification of the 1968 version of the International Standard Classification of Occupations (ISCO-68). (Leeuwen et al. (2004)). http://historyofwork.iisg.nl/index.php.

⁴https://www.camsis.stir.ac.uk/hiscam/

⁵Xie (2003, 1992); Hendrickx (2004) provide less theoretical introductions to the RCII model.

 $^{^{6}}$ In the HISCAM indices estimated using only data from one country, when a category was small and its score varied substantially from the category's score in the "universal" scale, its score was replaced by the average of the original score and the score in the "universal" scale.

 $^{^{7}}$ The HISCAM database has 1.2 m father-son occupational pairs, but 0.5 m of these come from Quebec, where the occupations are mostly in agriculture.

We carry out the index estimation separately using the father-son occupation associations, and the father-in-law son associations, and then take the average of these occupational rankings in forming the overall index. The correlation between the RCII index created using fathers and sons versus the RCII index using fathers-in-law and sons is 0.95.

The second new index, FOE-PCA, is constructed in part using a large genealogical database for England that has information on such outcomes as occupation, wealth at death, and educational status. It is a much more direct estimate of average socio-economic status by occupation. Nicely, it is constructed completely independently of the information underlying the FOE-RCII index.

People want occupational status indices in part to measure the degree of occupational status inheritance, and also to measure the degree of occupational status assortment in marriage. It is thus potentially problematic to compare status inheritance and marital assortment over time when the indices to measure this are estimated by maximizing both of these correlations. This occupational status index has one virtue in being completely independent from parent-child occupation correlations and also from marital occupation correlations. This index has 5 components.

- 1. Literacy rates by occupation, 1837-1879
- 2. Probate Rate by occupation, 1858-1939
- 3. Average log wealth at death by occupation, 1858-1939
- 4. Average attainment of higher education by occupation, 1800-1939
- 5. Proportion in schooling ages 12-18 by occupation, 1851-1939

Occupational literacy is estimated from 0.4 m observations of the signature literacy of grooms 1837-1879 and their occupations. The period 1837-1879 was used even though there is literacy data all the way to 1939 because after 1880 signature literacy rates for grooms are near 100% so that this measure contributes little information for 1880 and later. For marriages 1837-1879 only 64% of grooms could sign the register, so that this measure contributes significant information on educational status by occupation. This measure will discriminate more on the status of lower status occupation, since almost all men in higher status occupations will be literate.

The second measure, the probate rate, shows the fraction of men by occupation that had some wealth at death, for deaths 1858 and later. The third measure is the average ln wealth at death, measured relative to average estimate ln wealth at death for each decade in England. For those not probated wealth at death is taken as half the level of wealth at which probate was legally required in the year of death. These two wealth measures correlate highly. But the first better measures differences in wealth for occupations lower in the wealth distribution, while the second better measures wealth differences for higher status occupations.

The fourth measure is an indicator of what fraction of men by occupation attended university, or achieved an equivalent higher education such as medical training in a teaching hospital, or membership of an engineering society, or qualification as a chartered accountant. This again is a measure which discriminates more for higher status occupations. The final measure is whether the person was observed in schooling when recorded in a census or population register ages 12-18.⁸

We construct a composite index of our five occupational status variables using Principal Components Analysis (PCA).⁹ PCA, originally created by Pearson (1901), is a widely used technique to simplify multidimensional data, later developed by Hotelling (1933). PCA generates a linear transformations of the five status measures into a set of new variables: uncorrelated principal components. By construction, the first principle component captures the greatest variation possible by any single linear transformation. We use this first principal component as our unidimensional index of occupational status.

 $^{^{8}}$ The censuses of 1851-1911 give such information, as does the population register of 1939.

⁹Simple averaging would be inefficient as information would be lost by combining high variability measures, such as average wealth, with those with low variability such as education or literacy. PCA allows the data to tell us the weights that maximize variability, without reference to any target, or output, measure. In this way, PCA is a type of 'unsupervised learning'.

Marriage	All	Groom	Groom	Father	Father-in-law
Period		Literacy	Occupation	Occupation	Occupation
1837-59	540,650	289,772	450,905	413,638	411,789

Table 4.1: Parish Register Marriage Data, 1837-2021

4 Data

We use two sources of data to construct these new indices. The first is a set of 1.6 million marriage records in England 1837-1939 which were transcribed by volunteers to the Freereg organization, and posted on their web page.¹⁰ The Freereg marriage records, where the information comes from marriage record copies deposited in local record offices, all come from church weddings, and exclude civil marriages. But though Civil marriage was introduced in England in 1837, such marriages remained a small minority of all weddings before 1914. In 1841 Civil marriages were 1.7% of all marriages, in 1914, still only 24%, and in 1952 31% (Haskey, 2015).

These marriage registers typically record whether the bride and groom were literate (through their ability to sign the marriage register). They also give occupations for the groom, his father, and his father in law.¹¹ The data we have available by period is shown in table 4.1. Because transcribing these marriage records is a volunteer effort based on local interests, the numbers of marriages recorded by county for the years 1837-1939 varies considerably by county. Four counties contain about 50% of the marriages transcribed for England: Kent, Lancashire, Lincolnshire, and Staffordshire. But these counties were very different in terms of occupations and urbanization, so that the overall sample generated seems representative of England as a whole.

From these records we construct our FOE-RCII index of male occupational status 1837-1939. We also construct from the literacy data for grooms 1837-1879 a measure of literacy by occupation. The marriage records in table 3 for the years 1980-2021 came largely from deposited church marriage registers in Essex Record Office that we collected ourselves. In these years only a minority of all weddings were performed in churches. 49% of weddings by 1982 and 68% by 2012 were civil (Haskey, 2015). But there is no reason to expect that the father-son or father-in-law son correlations for church weddings would be any different than for the population as a whole.

In constructing the FOE-RCII index, and in estimating literacy by occupation we convert the more than 100,000 individual occupation description strings in these 1.6 million marriage records into 442 simplified occupations. The more than 2,000 different types of clerks listed, for example, were translated into Bank Clark, Civil Servant-Clerk, Clergy-Church of England, Commercial Clerk, Legal Clerk, and Parish Clerk. We also coded these occupations by their HISCO equivalent, and constructed a separate HISCO-RCII index. Where multiple occupations were given we used the first listed, except in the case that the first was a military occupation. In that case, we coded the person to their civilian occupation.

The second source of data we have is a genealogical database 1700-2022 of 414,000 linked persons in rare surname lineages (Families of England (FOE)) where we can obtain for a subsample of men their wealth at death, their probate status, their educational status ages 12-18, and their attainment of higher educational qualifications. Table 4.2 shows the amount of data available for men by occupation from this source. The quantity of data here is much smaller than for the marriage database, but we shall see that it produces an index which is nearly as good in terms of intergenerational correlations as is the family association index. These five measures of educational and wealth status correlate reasonably well, as

 $^{^{10}}$ We added to these records 21,339 marriages in Essex parishes 1837-1939 that we ourselves collected.

¹¹Much less often in earlier years they give an occupation also for the bride.

Birth Period	Occupation	Probate	LnWealth	Higher Education	Schooling 12-18
1780-1839 1840-1879 1880-1919	$12,367 \\ 16,045 \\ 14,264$	7,084 10,234 10,574	6,807 10,170 10,269	$11,774 \\ 15,507 \\ 13,585$	1,440 5,959 3,390
All	42,676	27,892	28,148	40,866	10,789

Table 4.2: FOE Social Status Data, Males

Figure 4.1: Correlation between Status Measures for occupations, 1800-1939

figure 4.1 shows.

The schooling 12-18 variable is estimated from a set of census reports on whether a person in this age range was at work, in schooling or an apprenticeship, or nothing was recorded. To allow for the cases with nothing recorded we take the raw measure of schooling as the average of an indicator variable for "in schooling" and one minus an indicator variable for "at work." However, we correct this variable for the average age people were observed at in each occupation by regressing the fraction in schooling against average age, and adjusting all the raw measures to a standard age of 15. This results in some cases in a negative estimate of the proportion in schooling on this adjusted measure.

The two wealth measures are the fraction of men who are probated at death by occupation, and the average log wealth of those probated normalized by average wealth at death for all men by decade 1850-1939.

The principal component analysis decomposition works well with the five status indices we employ here. The first principle component accounts for 68% of the variance in the five status measures. We normalize the resulting PCA index to a scale of 0-100. Figure 4.2 shows the distribution of the status values of the PCA index on this 0-100 scale, across the whole population of grooms. The distribution is asymmetrical, with the mass of men having occupations in the 20-50 occupational status range. But there is a long tail of upper status occupations in the 50-100 range. Table 4.3 shows the characteristics of the top 10 and bottom 10 occupations in the FOE-PCA ranking. The top and bottom occupations seem very plausible for those positions. Table 4.3 shows the ranking of the top 10 occupations in the FOE-RCII index, and their comparable ranking in the FOE-PCA index.

Though the FOE-RCII index and FOE-PCA index were produced using entirely different methods, and completely different data, they show a 0.86 correlation in the status assigned to occupations. Figure 4.4, for example, shows the estimated status of the 442 FOE simplified occupations on the FOE-PCA

Rank	Occupation	Probated	Wealth	Educated	Schooled	Literate	PCA

Table 4.3: Top and Bottom Ten Occupations, by Status

status index versus the FOE-RCII index. The figure also shows the most significant outliers. There is no obvious pattern to these. This, we believe, is a first demonstration that "family association" style status indices produce occupational status rankings that are very close to those implied using direct socio-economic measures such as education, earnings and wealth. This is confirmation of the validity of the HISCAM approach. This second index also produces much higher intergenerational correlations in occupational status than the existing indices. Where we estimate, however, familial correlations using the marriages database we potentially run into the problem that the FOE-RCII index was constructed using the same data and with an algorithm based on maximizing the father-son correlations in occupational status. However, we can test whether this will be a significant source of bias by taking the marriage data, divide it randomly into two halves, then estimating the FOE-RCII index on the first part. We can take this 50% index and estimate the father-son and father-in-law-son correlations using both the training 50% of the data, and the testing 50%. If these estimates do not differ significantly across the two sub-samples of the marriage data, then we will be getting an unbiased estimate of intergenerational mobility even using the marriage sample and the RCII status index from that sample.

Table 4.5 shows the results of this test. The evidence from the table is that there is no significant upwards bias in intergeneration correlation estimates when we use an RCII status index derived from the same data we are estimating the intergeneration correlation with. Thus on either database we can do a test of the quality of the different occupational indices.

Finally, using the HISCO occupational labels and the marriage registers database, we constructed a new HISCAM index for England 1837-1939, which we label HISCO-RCII. In constructing this index, because of the very large amounts of data, we do not drop diagonals and pseudo-diagonals. We do drop HISCO occupations with less than 20 men holding that occupation. Thus out of 1,300 HISCO occupations we end up assigning a status to only 363 in the HISCO-RCII index.

In appendix 2 we give the status scores of each of the 442 FOE occupations on both the FOE-RCII and FOE-PCA indices. In appendix 3 we give the HISCO-RCII scores, as well as the HISCAM-U2 and HISCAM-GB status scores, for the 363 occupations we are able to rank.

Figure 4.2: The Distribution of Occupational Status, FOE-PCA index

Notes: This is by occupational title, unweighted by the number of people in each occupation.

Rank	FOE-Occupation	RCII	PCA
1	Titled	100.00	96.08
2	Esquire	97.67	69.71
3	Member Of Parliament	96.79	98.42

 Notes: "Finl" indicates father-in-law.

5 Comparing the New Indices with HISCAM

Table 5.1 shows the correlation in occupational status as measured with the three new indices – FOE-RCII, FOE-PCA and HISCO-RCII – compared to HISCAM-GB and HISCAM-U2. As can be seen all these indices correlate strongly. Note in particularly that the FOE-PCA index, which is constructed both in a different way, and using separate data, correlates well with all the association type indices.

However, the measure of which is the best index of occupational status will be which index produces the highest correlations of son to father and groom to father-in-law. Table 5.2 shows these correlations for all five indices 1837-1939. Though the FOE-RCII index correlates well with the two HISCAM indices, the FOE-RCII index produces substantially greater father-son and father-in-law-son correlations than does either HISCAM-GB or HISCAM-U2. Thus on this criterion of fit, it is a better index of social status for England 1837-1939. The true correlation in status averages at least 0.67 for this period, well above the 0.53 found with HISCAM-GB.

The FOE-PCA index performs somewhat less well than the FOE-RCII index. But it must be remembered that 4 of the 5 sub-indices that compose this index were created using samples in the order of 10,000-50,000 as opposed to 2.4 million observations. If sample size for the FOE-PCA index was substantially increased it might well correlate better across generations than the FOE-RCII index.

Table 5.2 shows that on all these indices there appears to be an increase in social mobility rates 1837 to 1939. For the FOE-RCII index, for example, the measured father-son intergenerational correlation falls from 0.71 in 1837-1859 to 0.60 for 1900-39. On HISCAM-GB the fall is from 0.59 to 0.44.

However, the 0.67 intergenerational correlation recorded using the FOE-RCII index can be shown to be still well below the true correlation for 1837-1939. This is because of two forms of remaining error in the index. The first is the mismeasurement of the exact average status of each of the FOE 442 occupation categories. The second is that people whose occupation is assigned to the same of the 442 categories will often actually differ in occupational status. The category "clerk," for example, covers occupations that differ widely in earnings, and in other measures of occupational status.

Suppose a persons true occupational status is z. Suppose also their assigned status on an occupational index is Z. Then there will be two independent errors linking their assigned status to their true status. Z = z + u + e, where e is the error in measuring the true average occupational status of the assigned occupation Z. u is the error caused by the range of occupations that fall under the label Z, each with a different underlying status.

When we measure intergenerational mobility with such a social status index the estimate is biased downwards by a factor

$$\frac{\sigma_z^2}{\sigma_z^2 + \sigma_u^2 + \sigma_e^2} \tag{1}$$

For the FOE-RCII and FOE-PCA indices, because of their entirely independent construction, the error component e attached to errors in the average occupational status by category will be independent, but not the within-category component u. Assuming the error term e variance is the same for each index, the correlation between these indices 0.86 will be

$$\rho = \frac{\sigma_z^2 + \sigma_u^2}{\sigma_z^2 + \sigma_u^2 + \sigma_e^2} = 0.86 \tag{2}$$

This implies that the error component in these indices we have derived has to be at least 14% of the variance in measured status. It also implies that if we multiply our father-son correlations by 1.16 we will get an estimate closer, but still not as large as, the true underlying persistence of occupational status across generations. Since that correlation for the RCII index is 0.67, the true intergenerational correlation in occupational status has to be at least 0.78. When we add the attenuation caused by the variance within occupational categories, the true underlying correlation of occupational status in England 1837-1939 must be above 0.8. This is well above the 0.49-0.53 correlation reported for this period using the HISCAM-U2 and HISCAM-GB occupational status indices.

Measure	HISCAM	HISCAM	FOE	FOE	HISCO
	U2	GB	PCA	RCII	RCII
HISCAM U2 HISCAM GB FOE-PCA FOE-RCII HISCO BCU	1	0.872 1	$0.807 \\ 0.738 \\ 1$	$\begin{array}{c} 0.809 \\ 0.750 \\ 0.859 \\ 1 \end{array}$	$\begin{array}{c} 0.835 \\ 0.786 \\ 0.821 \\ 0.933 \\ 1 \end{array}$

 $\it Notes:$ "Finl" indicates father-in-law.

6 Measuring Social Mobility with Imperfect Status Indices

Above we developed two new social status indices for England and Wales 1800-1939. We see with those indices that intergenerational social mobility rates are much lower than conventionally estimated. There is more occupational status persistence than previous status indices show. But we also see on all the indices that there are signs of increases in social mobility over time as England industrialized. However, there remains the issue that all indices are imperfect measures of the true social status of individuals, and the degree of imperfection can change over time with changes in the structure of the economy, and changes in how occupations are described.

Here we show how we can use the marriage records in England to estimate measures of marital occupational status assortment and intergenerational occupational correlations that should be independent of these measurement errors.¹² Consider figure 6.1, which shows the pattern of correlations in occupational status between a groom, his father and his father-in-law, assuming that the matching in marriage is between groom and bride.¹³ The true correlations in occupational status between father and son, bride and groom, and bride and her father, are assumed to be b, r, and f.¹⁴

But the correlations, where observed, will be attenuated by measurement errors, measurement errors that vary with time and place. The attenuation will potentially be different where the pair observed is male, θ , as opposed to male and female, ϕ . Figure 6.1shows the observed correlations between father and son, father and father-in-law and son and father-in-law. The observed correlation in occupational status between groom and father, and groom and father-in-law will be θb and $\theta r f$. The observed correlation in occupational status between father and father-in-law will be $\theta r b f$. But this in turn implies that

$$b = \frac{correlation\ father - in - law\ to\ father}{correlation\ father - in - law\ to\ aroom} = \frac{\theta r b f}{\theta r f}$$
(3)

Thus by taking the ratio of the father-in-law to father and father-in-law to groom correlations we can get an estimate of the underlying intergenerational father-son correlation independent of measurement errors, even when these errors are changing over time periods.

Table 6.2 shows these intergenerational correlation estimates for father-in-law to groom and fatherin-law to father using the FOE-RCII status index for 1837-1939, and the CAMSIS index for 1940-2021.¹⁵ The measured father-in-law to groom correlation drops substantially in this period from 0.591 in 1837-79 to 0.285 by 1980-2021. This would in the literature cited above be taken as a sign of increasing social mobility rates. But the implied intergenerational father-son correlation shown in the table is close to 0.9 all they way from 1837 to 1979. Thereafter the point estimate drops to 0.780, though with a standard error now becuase of fewer observations of 0.029, so that the actual value could be in the range 0.72 to 0.84. Importantly the substantial decline in the father to son correlation shown in table 6.3, where the decline 1837-2021 is from 0.70 to 0.36 is not echoed in the estimate of the underlying father-son correlation which goes just from 0.90 down to 0.78.

Note that the underlying marital correlation in underlying social status will be given by

$$r = \frac{correlation\ father - in - law\ to\ groom}{correlation\ to\ groom} * \frac{b}{f} = \frac{\theta rf}{\theta b} * \frac{b}{f}$$
(4)

If daughters inherit underlying status as strongly as sons, so that b = f, then that underlying marital status correlation r will be just

$$r = \frac{correlation \ father - in - law \ to \ groom}{correlation \ to \ groom}$$
(5)

Table 6.3 shows what the underlying implied marital correlations were based on (5). As can be seen, despite again the declining measured father-son correlations, these implied marital correlations are high,

 $^{^{12}}$ Here we use a method first employed by Curtis (2020)

 $^{^{13}}$ Clark and Cummins (2022) show that for England 1837-2021 there is clear evidence that matching in marriage was between bride and groom.

¹⁴Brides often did not have any listed occupation in the English marriage records, but we can think of her having a latent occupational status, that the groom is matching with. There is other evidence suggesting that b = f, so that there is gender symmetry in the inheritance of (underlying) occupational status, but for the estimation of b we do not need to assume this. See again Clark and Cummins (2022).

 $^{^{15}\}mathrm{The}$ Camsis index used here is described in table 2.1, and is for 1991.

Figure 6.1: Correlations in Status in Marriage

and in this case stable throughout the years 1837-2021, lying always in the range 0.80 to 0.83. This very high implied assortment in marriage throughout these years is consistent with the high intergenerational correlation estimated across these same years.¹⁶

Thus despite the observed substantial decline over time in father-son, father to father-in-law, and father-in-law to son correlations, the correlation patterns observed are largely consistent with a both very high levels of assortment by status in marriage, and a subsequent very strong intergenerational correlation in status. The observed correlations also suggest no change over time in the strength of marital assortment, despite the rise in female education and employment across these years. Intergenerational mobility in status is very limited throughout, with just a modest increase observed in the very last period.

The methods used here to correct for measurement errors can be widely adopted where marital records record status information for grooms, and both fathers. In England, for example, the Registrar General holds over 100 million such marriage records 1837-2022.

7 Conclusion

This paper reports multiple outcomes. First, using large quantities of new data, we construct three new independent occupational status indices for England in the years 1800-1939, the FOE-RCII, FOE-PCA, and HISCO-RCII indices. These new indices all provide more accurate measures of the social status of occupations in these years than the existing HISCAM indices. The appendices give the estimated status value for all occupations on these new indices.

Second we validate that association indices of occupational status do successfully capture the socioeconomic rank of different occupations as measured by the educational and wealth status of the holders. Third we show how dependent measures of intergenerational occupational status mobility are to the quality of occupational indices. The more accurate the index the lower will be measured rates of intergenerational mobility. This makes all comparisons of intergenerational occupational mobility over time and place suspect. The measurement errors embedded in occupational status indices depend on the quantity of data available to construct the index, the employment structure in the society in question, and the way occupations are described in different societies. Traditional comparisons of social mobility across time and place using such indices is unreliable.

Lastly we show how to derive measures of the true underlying father-son occupational status correlation, independent of measurement errors, using the occupational status of fathers, sons and fathers-in-law. This underlying father-son correlation is remarkably high, in the region of 0.9 for all periods but the most recent, marriages 1980-2021, where it is around 0.78. But we see from the FOE-RCII index that for the period 1837-1879 the implied correlation in underlying occupational status father-son has to be greater than 0.8. So at least in this first period we can validate these new estimates.

A Appendix

A.1 Principal Component Index

We construct a composite index of our five occupational status variables using Principal Components Analysis (PCA).¹⁷ PCA is a widely used technique to simplify multidimensional data, originally developed by Pearson (1901), and Hotelling (1933). We employ PCA to generate linear transformations of the five status measures into a set of new variables; uncorrelated principal components. By construction, the first principle component captures the greatest variation possible by any single linear1997 transformation, and thus we use this as the basis for our unidimensional index of occupational status.

Formally we take a vector of scaled status variables \mathbf{x} with covariance matrix $\boldsymbol{\Sigma}$ where the first principle component is $\alpha'_1 x$ where α_1 is the eigenvector of $\boldsymbol{\Sigma}$ corresponding to the largest eigenvalue, λ_1 .¹⁸

Table A.1 reports the relative importance of each of the principal components calculated on the set of five occupational status measures. The first Principal Component accounts for 68.1% of the variance in the five status measures. This supports the validity of using this first principal component as the basis of our unidimensional status index. The variable loadings (Eigenvectors) are reported in table A.2.

	Principal Component					
	1	2	3	4	5	
Standard deviation	1.832	0.813	0.734	0.606	0.279	
Proportion of Variance	0.671	0.132	0.108	0.073	0.016	
Cumulative Proportion	0.671	0.803	0.911	0.984	1.000	

Table A.1: Importance of Principal Components

Table A.2: First Princi	pal Component	Eigenvectors
-------------------------	---------------	--------------

Measure	Loading
Probated	-0.490
Wealth	-0.501
Educated	-0.405
Schooled	-0.424
Literate	-0.407

Figure A.1 reports a biplot which illustrates how each of the five variables relate to each other in the PCA. All five component measures contribute to the first Principal Component, and are relatively close to one another. (In particular, the probated measure, and that for average, wealth). There is a surprising distance between the average literacy rate of an occupation, and the schooling and higher education variables. This relates to their respective correlations, as reported in figure 4.1.

Finally we re-scale the First Principal component score into a standardized status score, from 0-100. Note we do not calculate percentiles here but rather rescale the first principal component so that the minimum is 0, and the maximum is 100. The top 10, and the bottom 10, by this score (calculated to one decimal place) is reported in table 4.3. The distribution of this score is reported in figure 4.2.

A.2 Tabular Summary of the FOE-PCA and FOE-RCII Indices

Appendix table A.3 shows the five components of the PCA index for 442 FOE occupational categories, as well as the final PCA index and the RCII index. The occupations are listed in alphabetical order. For 40 of the 442 occupations one or more of the components of the PCA index is missing. In these cases

¹⁷Simple averaging would be inefficient as information would be lost by combining high variability measures, such as average wealth, with those with low variability such as education or literacy. PCA allows the data to tell us the weights that maximize variability, without reference to any target, or output, measure. In this way, PCA is a type of 'unsupervised learning'.

¹⁸For more details on the derivation of Principal Components, see Jolliffe (2002) p.4-6.

Figure A.1: PCA Biplot of the Five Status Measures and the First and Second Principal Component Source: PCA analysis.

the PCA index values were interpolated based on the other components. For one occupation, "scissor smith", there was not sufficient data to estimate the RCII index value.

A.3 Tabular Summary of the HISCO-RCII Index

Appendix table A.4 shows the RCII index for HISCO categories, as well as the HISCAM U2 index and the HISCAM GB index. The occupations are listed in order of the HISCO codes.

Table A.4: HISCO Indices

1110 Obmist, General 63.7 82.8 84.1 1100 Other Chemist 58.7 82.8 84.1 1210 Physicist, General 71.4 79.7 80.4 1300 Other Physical Science Technicians, Specialisatin Unknown 48.2 62.4 66.6 1420 Obmistery Technician 38.3 79.7 80.4 2000 Engineer, Specialisation Unknown 46.4 99.0 66.8 2120 Dighter, Specialisation Unknown 46.3 84.6 67.4 2200 Civil Engineer, General 65.3 84.5 65.0 2305 Electrical Engineer, General 54.6 81.8 82.8 2400 Mechanical Engineer, General 54.6 81.8 82.8 2410 Mining Engineer, General 54.6 81.8 82.8 2710 Mining Engineer, General 63.3 67.1 66.0 2700 Mining Engineer, General 50.7 53.5 54.2 2110 Mining Engineer, General 50.7 53.5 54.2 2100 Mining Engineer, General 50.7 53.5 54.2 2100 Mining Engineer, General 50.7 53.5 54.2 2100 M	Occupation	RCII	HISCAM U2	HISCAM GB
